A parent's genes that contain a mutation can transcribe with RNA which can then translate into a protein that may act differently than intended. One way this could happen is if a protein places at a nerve ending increasing or decreasing the availability of needed neurotransmitters such as serotonin and dopamine (Sullivan, 2000).

What Gene Causes Depression?

Despite common belief depression is not linked to a single gene in particular, in fact, many genes can carry a genetic mutation, however some genes carry higher likelihood of carrying a mutation than others. Chromosome 3p25-26 has been found to be closely linked to depression as many families carrying this certain chromosome have had many people with severe depression. However this is simply one of the many genes that could possibly be associated with depression (Breen, 2011).
What is Epigenetics and How Does It Affect Depression?

Epigenetics performs an important function in the development and manifestation of despair. Epigenetics refers to adjustments in gene expression that arise without changing the genomic DNA series. These modifications may be influenced by numerous environmental elements, together with stress, trauma, nutrition, and life-style. In the context of depression, epigenetic adjustments can affect genes involved in temper regulation, stress reaction, and neurotransmitter signaling. For instance, increased tiers of strain can cause epigenetic modifications that silence genes’ effect on reducing emotional resilience, while activating genes associated with irritation and anxiety. Moreover, epigenetic modifications can also be transferred down from one generation to another, potentially predisposing people to depression primarily based on their ancestors’ lifestyles (Penner-Goeke, 2019).
